(57) **ABSTRACT**
A steerable guidewire. The steerable guidewire is fabricated includes an outer tube, an inner tube, a hub, and a distal articulating region. The steerable guidewire hub can be removed to permit advancement of catheters over its proximal end followed by re-attachment of the hub to permit deflection of the distal end of the steerable guidewire.

STEERABLE GUIDEWIRE AND METHOD OF USE

This application is a continuation-in-part of PCT Application PCT/US2013/073262, filed Dec. 5, 2013, which claims priority to U.S. application Ser. No. 13/750,689, filed Jan. 25, 2013 and U.S. Provisional Application 61/734,297, filed on Dec. 6, 2012, the entire contents of each of which are hereby incorporated herein by reference.

FIELD OF THE INVENTIONS

The inventions described below relate the field of guidewires.

BACKGROUND OF THE INVENTIONS

During certain interventional procedures that are directed at cardiac access, the patient is catheterized through an access point in a vein or artery. A catheter is routed to the heart or other region of the cardiovascular system through the access point, which may be created by a cutdown or a percutaneous access procedure. The catheter may be routed to a target location within the heart, cerebrovasculature, or other region of the cardiovascular system. The routing is typically performed using a percutaneous access procedure, in some cases called a Seldinger procedure. In other vascular access procedures, open surgical access is required. In either case, a guidewire is advanced into the vasculature by way of the percutaneous or open procedure. The guidewire serves as a tracking system over which a catheter can be routed to a target site within the patient. Guidewires can be used for procedures such as transcatheter, endovascular, or vascular access as well as for transcatheter, laparoscopic, thoracoscopic, and intramuscular access, and the like.

A pre-bent guidewire can be routed through the vasculature, in conjunction with a guide catheter to permit orienting the pre-bent distal tip of the guide catheter in the correct direction when a bifurcation or other directional deviation occurs in the vasculature.

SUMMARY OF THE INVENTIONS

A guidewire is disclosed wherein the guidewire is capable of articulating, steering, bending, deflecting, or otherwise being controlled off-axis to permit tracking within a vessel or body tissue, or moving to within a certain target location within a hollow organ. This articulation or steering can be performed without interaction with any guide catheters.

The steerability, deflection, or articulation, of a distal region of the guidewire device can be accomplished using the inner tube and outer tube, concentrically arranged and radially constrained together in the distal region of the guidewire. The inner tube outer diameter is a close tolerance fit to the inside diameter of the outer tube but the inner tube is free to translate along a longitudinal axis of the tubes relative to the outer tube. Thus, only translational motion along the longitudinal axis is used to generate the articulation. The inner tube is modified in a region proximate the distal end such that the inner tube is divided, weakened, or split, into two or more parts along a generally longitudinal direction. Only a portion of these divided parts of the inner tube are affixed, at their proximal end, to the more proximal portion of the inner tube. The parts of the inner tube not affixed at their proximal end can be optionally affixed near their distal end to the portions of the inner tube that are also affixed at their proximal end. The outer tube is rendered

flexible by cutting slots or gaps generally having a lateral or radial orientation, although there can be some projection at an angle or along the longitudinal axis of the outer tube. These lateral slots do not pass completely through the outer tubing so a spine with ribs is formed in the outer tubing. The outer tube can be formed as a helix or a coil having a finite spacing between the coils or windings along one or more sides of the distal region. A backbone or series of locking devices can optionally be added to prevent longitudinal compression or expansion on one side of the winding or coil in this configuration. As used herein, the coil construction embodiment having a backbone or fixation column is used interchangeably with embodiments where the distal part of the outer tube which is rendered flexible by way of a plurality of cuts, lateral slots, or the like.

The inner tube can be affixed to the outer tube at a region distal to the lateral slots in the outer tube (the flexible region of the outer tube). The portion of the inner tube that is affixed to the outer tube is that portion of the split inner tube that is connected at its proximal end to the more proximal portions of the inner tube. The inner tube can be configured with an asymmetric distal end, and is preferably split along its length at the distal end. The split is oriented so that it radially migrates toward and through the side of the inner tube on one side. This configuration leaves a connected side and a disconnected side to the inner tube. The disconnected side can be affixed to the connected side near the distal end by a bridge.

Thus, articulation is generated using a plurality of (two or more) nested, radially constrained, substantially concentric axially translating tubes, wherein a first tube is weakened on one side to increase flexibility and limit final curvature and shape while a second tube is split substantially longitudinally and broken off on one side within the region where the first tube is also weakened. Both tubes are substantially in place to maintain hoop strength, column strength, kink resistance, and orientation of discreet structures, such as breaks or slots exist within the plurality of tubes.

The proximal parts of the guidewire can comprise an outer tube that is of standard, unbroken cylindrical configuration with one or more intermediate tubes fabricated from cylindrical tubes of different bendability, cylindrical tubes having flexibility enhancing slots cut therein, closed coils, braided windings, or coils being somewhat open between the windings. The proximal region of the inner tube can be affixed to a solid structure or a wire rather than a tube.

The steerable guidewire can be fabricated to benefit in diameters ranging from about 0.010 inches to about 0.038 inches. They can come in various stiffnesses and tip shapes. The guidewire can be made available in undeflected tip configurations such as, but not limited to, a floppy, straight tip, a J-curve tip, and a slight curve tip, for example. The length of a guidewire can range from about 50-cm to about 250-cm or longer. The steerable guidewire can be beneficially, typically twice as long as a catheter which is to be loaded over the guidewire so that the guidewire can remain gripped by the user at both its proximal and distal ends with the catheter fully inserted over the guidewire. A guide catheter can be used in conjunction with the guidewire to achieve some steerability. For example, a guidewire with a curved tip can be withdrawn into a guide catheter to achieve a straight configuration, then be advanced outside the guide catheter into its curve and advanced into a vessel or body lumen, wherein the guide catheter is then advanced along the guidewire until the next steering event is required. The tip curving can be generated by articulation in situ, rather than pre-curving.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1A illustrates a side, partial cutaway view of a steerable guidewire having a hub, a proximal region, an intermediate region, and a steerable distal region.

FIG. 1B illustrates a magnified side, partial breakaway view of a transition between the distal steerable region and the intermediate region of the steerable guidewire of FIG. 1A.

FIG. 2A illustrates a side, partial breakaway, view of an outer tube of a steerable guidewire comprising a plurality of slots near the distal end to generate a region of increased flexibility.

FIG. 2B illustrates a side, partial breakaway, view of an inner tube of the steerable guidewire comprising a longitudinal slot dividing the tube into two axially oriented parts which are connected at the distal end of the inner tube.

FIG. 3 illustrates a cross-sectional view of the proximal end of the steerable guidewire comprising a stopcock and a bend adjusting mechanism.

FIG. 4 illustrates a partial breakaway view of the distal end of the steerable guidewire comprising the outer tube and the inner tube arranged concentrically and oriented circumferentially.

FIG. 5 illustrates an oblique view of the proximal end of the steerable guidewire.

FIG. 6 illustrates a side view of the distal end of the steerable guidewire incorporating the inner split tube and the outer T-slotted tube with the inner tube being pulled proximally relative to the outer tube causing the outer tube to deform into a curve.

FIG. 7A illustrates a top view of a portion of the distal flexible region of an outer tube comprising dovetails or interlocking grooves to reduce torque or side-to-side motion.

FIG. 7B illustrates a side view of a portion of the distal flexible region of an outer tube comprising dovetails or locking grooves to reduce torque or side-to-side motion.

FIG. 8 illustrates the distal end of a steerable guidewire advanced nearly to the distal end of an obturator or dilator, which is coaxially, removably assembled into the central lumen of a guide catheter sheath.

FIG. 9A illustrates an outer tube cut in its flexible regions with shorter lateral slots and with reduced or complete elimination of some T-slots to improve resistance to bending in that region.

FIG. 9B illustrates an inner tube wherein the disconnected side has been removed, leaving only the connected side and the distal end.

FIG. 10A illustrates a cross-sectional view of a tubing configuration in a steerable guidewire within the flexible region, wherein the separation slot in the inner tube is substantially at the midpoint or center of the inner tubing.

FIG. 10B illustrates a lateral cross-section of a tubing configuration of a steerable guidewire within the flexible distal region, with an off-center slot.

FIG. 11 illustrates a side, partial cutaway view of the distal end of a steerable guidewire wherein the outer tube comprises a coil or helix with a small amount of space between the windings.

FIG. 12 illustrates a side, partial cutaway view of the distal end of a steerable guidewire wherein the outer tube comprises a cut tube having a backbone and ribs.

DETAILED DESCRIPTION OF THE INVENTIONS

The steerable guidewire is an endoluminally, transvascularily, or endovascularly placed steerable guidewire, with

internal deflectability or the ability to articulate, at its distal end, in a direction away from its longitudinal axis. The steerable guidewire is generally fabricated from stainless steel, nitinol, or the like and comprises an outer tube, an inner tube, and a distal articulating region. The deflecting or articulating mechanism is integral to the steerable guidewire. The steerable guidewire is useful for animals, including mammals and human patients and is routed through body lumens or other body structures to reach its target destination. A guidewire is a wire, composite wire or spring used as a guide for placement of a catheter. A guidewire is structurally distinct from other elongate structures associated with catheters, such as punches, delivery wires, etc., in that it is characterized by sufficient column strength that it can be pushed, from the proximal end, to force the distal tip through the vasculature of a patient, while the distal tip is flexible enough to be deflected by blood vessel wall so that it may impinge on the blood vessel walls during passage without deforming, puncturing or injuring the blood vessel. Typical guidewire diameters for cardiovascular use have diameters in the range of 0.010" to 0.018" to 0.025", a length in the range of 100 to 300 cm, and a tip stiffness of 1 to 10 grams for access to unoccluded vessels and 10 to 30 grams for crossing occluded or stenosed vessels. Tip stiffness is measured by the amount of force/weight needed to deflect the tip by 45%. Peripheral guidewires are larger in diameter (in the range of about 0.032", 0.038", or greater, and may have a higher tip stiffness). Preferably, a flexible guidewire constructed as described herein will have a tip stiffness as measured in grams, of 1 to 30 grams. For some applications, such as coronary access, the tip will be floppier (have a lower stiffness) than the major length of the guidewire, while in other applications, such as aortic access, the tip and major length may have substantially similar stiffness. The floppy tip, where provided, may extend 0.5 to 10 cm, and preferably 1 to 5 centimeters at the very distal end of the guidewire.

The stiffness of the guidewire major length and guidewire tip may also be expressed in relation to flexural modulus (bending modulus). Preferably, a flexible guidewire constructed as described herein will have a flexural modulus in certain range, for example 8 to 10 gigapascals, along its major length. If a floppy tip is provided, the floppy tip will have a flexural modulus in the range of 100% to 10% of the major length, for example 0.8 to 10 gigapascals. A "stiff" guidewire may have a flexural modulus of about 16 to 20 gigapascals, while an extra-stiff guidewire may have a flexural modulus of 28 to 32 gigapascals, and an extra-stiff guidewire may have a flexural modulus of 50 to 70 gigapascals. The tip of guidewires with these higher flexural modulus, if "floppy" vis-à-vis the major length of the guidewire, may be a flexural modulus of 10% to 90% of the major length. These structural characteristics distinguish the guidewire from other structures such as punches, ultrasound catheters and other such structures which are not suitable for unsheathed navigation through the vasculature of a patient, and are not suitable for guiding a catheter through the vasculature.

The steerable guidewire comprises an inner tube and an outer tube. The steerable guidewire can also comprise a stylet or obturator, which can be removable or non-removable. The steerable guidewire further comprises a hub at its proximal end which permits grasping of the steerable guidewire as well as features, or control mechanisms, for controlling the articulation at the distal end. Such features can comprise control knobs, handles, levers, or the like. The proximal end further can optionally be terminated with a female Luer or Luer lock port or hemostasis valve, which is

suitable for attachment of pressure monitoring lines, dye injection lines, vacuum lines, a combination thereof, or the like. The steerable guidewire can comprise a center channel operably affixed to the Luer or Luer lock port, said channel being useful for dye injection, material or fluid administration or removal, pressure monitoring, or the like. It may be beneficial that a catheter be advanceable over the guidewire beginning at the proximal end of the guidewire (in over-the-wire fashion). To accommodate over-the-wire use, the hub, which comprises controlling mechanisms for the distal deflection, is beneficially detachable from the guidewire and can be releasably or non-releasably affixed to the guidewire following advancement of a catheter past the proximal end of the guidewire.

The steerable guidewire is fabricated so that it is substantially straight from its proximal end to its distal end. Manipulation of a control mechanism at the proximal end of the steerable guidewire causes a distal region of the steerable guidewire to bend or curve away from its longitudinal axis. The bending, steering, deflecting, or articulating region is located near the distal end of the steerable guidewire and can be a flexible region or structure placed under tension or compression through control rods or tubular structures routed from the control handle at the proximal end of the steerable guidewire to a point distal to the flexible region.

One method of use involves inserting the central core wire or stylet so that it protrudes out the distal end of the steerable guidewire. A percutaneous or cutdown procedure is performed to gain access to structures such as, but not limited to, the vasculature, either a vein, an artery, a body lumen or duct, a hollow organ, musculature, fascia, cutaneous tissue, the abdominal cavity, the thoracic cavity, and the like. An introducer, which is usually a hollow, large diameter, hypodermic needle, and the steerable guidewire are placed within the vasculature and the steerable guidewire is routed proximate to the target treatment site. The introducer can be removed at this time or substantially at the time the guidewire is introduced into the body lumen. A guiding catheter, preferably with a removable central obturator or dilator having a core lumen sized to slidably fit over the steerable guidewire, with a tapered distal tip pre-inserted, is routed over the steerable guidewire to the target site. The steerable guidewire can be adjusted so that it assumes a substantially straight configuration. The steerable guidewire can be advanced through the central lumen of an already placed catheter, sheath, introducer, or guide catheter. The steerable guidewire comprises a generally atraumatic, non-sharp, distal tip. The distal tip can be rounded, oval, or the like.

The distal end of the steerable guidewire, and optionally the body of the guidewire as well, is sufficiently radiopaque that it is observable clearly under fluoroscopy or X-ray imaging. The steerable guidewire, especially near its distal end, can be configured with asymmetric radiopaque markers that provide some indication regarding the side of the steerable guidewire that deflection can occur. The location of the steerable guidewire and the amount of deflection and curvature of the distal end are observed and controlled using the aforementioned fluoroscopy or X-ray imaging, or other imaging method such as MRI, PET scan, ultrasound imaging, and the like. One or more radiopaque markers can be affixed to the distal end of the steerable guidewire to further enhance visibility under fluoroscopy. Such radiopaque markers can comprise materials such as, but not limited to, thick ferrous metals, tantalum, gold, platinum, platinum iridium, and the like.

Deflection of the distal tip to varying degrees of curvature, under control from the proximal end of the guidewire can be

performed. The curve can be oriented along the direction of a branching vessel or vessel curve so that the steerable guidewire can then be advanced into the vessel by way of its high column strength and torqueability. Alignment with any curvature of the catheter can be completed at this time. When correctly positioned under fluoroscopy, ultrasound, or other imaging system, dye can be injected into the central lumen of the steerable guidewire at its proximal end and be expelled out of the distal end of the steerable guidewire to provide for road-mapping, etc. This steering function can be very beneficial in device placement and is also especially useful in highly tortuous vessels or body lumens which may further include branching structures such as bifurcations, trifurcations, and the like.

The inner tube, the outer tube, or both can have slots imparted into their walls to impart controlled degrees of flexibility. The slots can be configured as "snake cuts" to form a series of ribs with one or more spines. The spines can be oriented at a given circumferential position on the outer tube, the inner tube, or both. The spines can also have non-constant orientations. In some embodiments, only the outer tube is slotted. The slots can be generated within the distal portion of the outer tube where the curve is generated. This distance can range between about 0.5-cm and 15-cm of the end and preferably between 1-cm and 5-cm of the distal end. The slot widths can range between 0.001 inches and 0.100 inches with a preferable width of 0.003 to 0.010 inches, and more preferably the slot widths are about 0.008 inches. It may be desirable to have the outer tube bend in one direction only but not in the opposite direction and not in either lateral direction. To accommodate this operability, the slots can be made on one side of the outer tubing within, for example, the distal 10-cm of the tube length, while the opposite side is left intact without slots. Approximately 5 to 30 cuts can be generated with a width of approximately 0.010 to 0.040 inches. The cut depth, across the tube diameter from one side, can range between 0.1 and 0.9 of the tube diameter. Preferably, the cut depth can be approximately 0.4 to 0.6 of the tube diameter with a cut width of 0.025 inches. A second cut can be generated on the opposite side of the tube wherein the second cut is approximately 0.005 inches or less. The outer tube can be bent into an arc first and then have the slots generated such that when the tube is bent back toward the 0.005 inch wide cuts, the tube will have an approximately straight configuration even through each tube segment between the cuts is slightly arced or curved.

FIG. 1A illustrates a side view of a steerable guidewire **100** comprising a distal outer tube **102**, an inner control tube or rod **104**, an outer low-friction coating **106**, an intermediate outer tube **108**, a proximal outer tube **110**, a hub body **112** further comprising a hub body lumen **124**, a jackscrew traveler **114**, a control knob **116**, a guidewire tip **118**, an inner tube lock **120**, and a proximal outer tube lock **122**.

Referring to FIG. 1A, the distal end of the inner control tube or rod, hereafter called the inner tube, **104** is affixed to the distal end of the distal outer tube **102** with a weld, adhesive bond, fastener, fixation device, or the like. The inner control tube or rod **104** is slidably disposed within the inner lumen of the distal outer tube **102** except at the distal end where they are affixed to each other. The proximal end of the distal outer tube **102** is affixed to the distal end of the intermediate outer tube **108** by a weld, fixation device, adhesive bond, or the like. The proximal end of the intermediate outer tube **108** is affixed to the distal end of the proximal outer tube **110** by a weld, fixation device, adhesive bond, or the like. The entire outer tube assembly **102**, **108**,

110 can be covered with an optional anti-friction coating or layer 106. The guidewire tip 118 or nose cone is affixed to the inner tube 104, the distal outer tube 102, or both. The guidewire tip 118 can comprise a through hole to permit infusion of fluids therethrough or for advancement of a stylet (not shown) beyond the distal end of the guidewire 100. The control knob 116 is rotationally free to move within the hub body 112, to which it is longitudinally affixed and the two components do not move axially relative to each other. The jackscrew traveler 114 can move axially within a lumen 124 within the hub body 112 within the constraints of the end of the internal lumen 124 of the hub body 112. The jackscrew traveler 114 is keyed within the lumen 124 by a non-round cross-section that impinges on complimentary structures within the lumen 124 to prevent relative rotational movement of the two components 112, 124. The jackscrew traveler 114 comprises external threads that are complimentary and fit within internal threads of the control knob 116. Thus, when the control knob 116 is turned, the jackscrew traveler 114 is forced to move axially either forward or backward because the control knob 116 is longitudinally affixed within the hub body 112.

A thread pitch for the jackscrew traveler 114 and the control knob 116 can range from about 16 to about 64 threads per inch (TPI) with a preferred range of about 24 TPI to about 48 TPI and a more preferred range of about 28 to about 36 TPI.

The hub assembly may be removable from the steerable guidewire so that the proximal end of the steerable guidewire 100 retains the same (or smaller) diameter or profile as the intermediate and distal ends of the guidewire. Catheters, guide catheters, introducers, sheaths, or other axially elongate medical devices comprising an internal guidewire lumen can be slipped over the proximal end of the steerable guidewire and advanced into the patient over an already placed steerable guidewire. This approach provides for catheter exchange, replacement, swapping, or the like. Once the catheter is advanced such that its proximal end is located distal to the proximal end of the steerable guidewire, the hub assembly can be releasably affixed to the proximal end of the steerable guidewire so that the distal end of the guidewire can be deflected under control at the proximal end. The hub assembly illustrated in FIG. 1A provides an outer tube lock 122 and inner tube lock 120 to secure the outer tube 110 and inner tube 104 of the steerable guidewire such that the hub is affixed and in control of the relative axial position of the two tubes. The outer tube lock 122 can be configured as a bayonet mount (as illustrated) or it can comprise a locking button, locking clamp, threaded lock, or the like.

FIG. 1B illustrates a magnified view of the steerable guidewire 100 of FIG. 1A at the transition between the distal end of the intermediate region 108 and the proximal end of the distal, steerable region. The steerable guidewire 100 transition region comprises the intermediate outer tube 108, the distal outer tube 102, the inner tube 104, and the polymeric outer coating 106.

The polymeric outer coating 106 is optional but beneficial and can comprise materials such as, but not limited to, fluoropolymers such as PTFE, PFA, FEP, polyester, polyamide, PEEK, and the like. The polymeric outer coating 106 can render the coiled embodiment of the intermediate outer tube 108, as illustrated, to retain a relatively smooth exterior surface and provide for friction reduction which is useful when passing a long, slender guidewire through a long, catheter lumen. The distal outer tube 102 can be affixed to the intermediate outer tube 108 by means of a weld, fastener, adhesive bond, embedment with polymeric, metallic, or

ceramic materials, or the like. The intermediate outer tube 108, illustrated in this embodiment as a coil structure with substantially no spacing between the coils, is highly flexible and the flexibility can be controlled by the elastic modulus, thickness, and other material properties of the outer coating 106. The intermediate outer tube 108, in other embodiments, can comprise structures such as, but not limited to, an unperforated or unfenestrated tube, a tube with partial lateral cuts, a spiral cut tube, a ribcage with a backbone, or the like.

FIG. 2A illustrates a side view, in partial breakaway, of the distal end of the axially elongate distal outer tube 102, comprising a lumen 214, a proximal, uncut portion 212, a plurality of lateral partial cuts 216, and a plurality of longitudinal "T" cuts 218. The distal outer tube 102 serves as the outer tube of the steerable guidewire such as that illustrated in FIG. 1. The plurality of partial lateral cuts 216 serve to render the region of the outer tube 102 in which the lateral cuts 216 are located more flexible than the proximal region 212. The plurality of longitudinal "T" cuts, serve to further render the region of the outer tube 102, in which the "T" cuts 218 reside, more flexible than in tubes where such "T" cuts 218 were not present. The longitudinal "T" cuts 218 are optional but are beneficial in increasing the flexibility of the outer tube 102 in the selected bend region. The partial lateral slots 216 can be spaced apart by about 0.02 to about 1.0 inches with a preferred range of about 0.1 inches to about 0.8 inches and a further preferred range of about 0.15 inches to about 0.5 inches. In an exemplary embodiment, the partial lateral slots 216 are spaced about 0.17 inches apart. The spacing between the partial lateral slots 216 can vary. The spacing between the partial lateral slots toward the proximal end of the outer tube 102 can be about 0.3 inches while those partial lateral slots 216 nearer the distal end of the outer tube 102 can be spaced about 0.15 inches apart. The spacing can change in a step function, it can change gradually moving from one end of the outer tube 102 to the other, or it can increase and decrease one or more times to generate certain specific flexibility characteristics. Increased spacing increases the minimum radius of curvature achievable by compression of the partial lateral slots 216 while decreased spacing allows for a smaller minimum radius of curvature.

The number of lateral cuts 216 or, optionally, the number of lateral cuts 216 with T-cuts 218 can number between about four and about 50 with a preferred number being between about six and about 25 and a more preferred number of about eight to about fifteen. In the illustrated embodiment, there are 12 partial lateral cuts 216, each modified with a "T" slot 218. In other embodiments, the partial lateral cuts 216 can be shaped differently. For example, the partial lateral cuts 216 can be at angles other than 90 degrees to the longitudinal axis, curved, V-shaped, Z-shaped, W-shaped or the like. In other embodiments, the "T" slots 218 can have, for example, further cuts approximately lateral to the longitudinal axis, along any portion of the "T" cut 218. This construction provides the outer tube with a flexible region at its distal end. The flexible region is a region at the distal end of the outer tube that is significantly more flexible and susceptible to deflection than the remaining proximal region of the outer tube.

The outer tube 102 can have an outer diameter of about 0.010 to about 0.1 inches with a preferred outside diameter of about 0.015 to about 0.050 inches and a more preferred diameter of about 0.020 inches to about 0.035 inches. In the illustrated embodiment, the outside diameter is about 0.048 inches while the inner diameter is about 0.036 inches. The inside diameter of the outer tube 102 can range from about 0.0005 inches to about 0.090 inches.

FIG. 2B is a side view, in partial breakaway, of the distal end of an axially elongate inner tube **104**, comprising a lumen **224**, a proximal, uncut portion **222**, a longitudinal slot **226** further comprising an angled lead in **228**, a free side **234**, a pusher or connected side **232**, and a distal tip **230**. The distal tip **230** interconnects the free side **234** and the pusher side **232**. The distal tip **230** or end of the inner tube **104** can further comprise a rounded, tapered, or blunted tip or nose cone (not shown). The disconnected free side **234** and the connected pusher side **232** are generally integrally formed but can also be affixed to each other by welding, adhesives, fasteners, or the like.

The lead in **228** to the longitudinal slot **226** is beneficially angled to prevent other guidewires, stylets, or other devices, which are inserted through the central lumen **224** from being caught or bumping against an edge. The angled lead in **228** serves a guide to assist with traverse of a stylet, obturator, or guidewire past the lead in **228** and into the distal region of the steerable guidewire. The lead in **228** can be angled from between about -80 degrees (the angle can be retrograde) from the longitudinal axis (fully lateral) to about $+2$ degrees and preferably from about $+5$ degrees to about $+20$ degrees with a most preferred angle of about $+8$ degrees and about $+15$ degrees. In the illustrated embodiment, the angle of the lead in slot **228** is about 10 degrees from the longitudinal axis. A second feature of the lead in **228** is that it be positioned or located proximally to the most proximal "T" slot **218** in the outer tube **102** when the two tubes **102**, **104** are affixed to each other (see FIG. 9). The lead in **228** is located at least 1-cm proximal to the proximal most "T" slot **218** and preferably at least 2-cm proximal to the proximal most "T" slot **218** so that bending in the distal region does not distort the lead in **228** and cause kinking, misalignment, or pinching of the internal lumen **224**.

The inner tube **104** can have an outside diameter that is slightly smaller than the inside diameter of the outer tube **102** so that the inner tube **104** can be constrained to move longitudinally or axially within the outer tube **102** in a smooth fashion with relatively little force exerted. In the illustrated embodiment, the outside diameter of the inner tube **104** is about 0.033 inches giving about a 0.0015 inch radial clearance between the two tubes **102** and **104**. The inside diameter of the inner tube **104** can range from about 0.006 to about 0.015 inches less than the outside diameter of the inner tube **104**. In the illustrated embodiment, the wall thickness of the inner tube is about 0.006 inches so the inside diameter of the inner tube is about 0.021 inches. The lumen **224** of the inner tube **104** can be sized to slidably accept a stylet or obturator **140** such as illustrated in FIGS. 1 and 2. A typical stylet wire **140** can range in diameter from about 0.01 to about 0.23 inches with a preferred diameter range of about 0.012 to about 0.020 inches. In another embodiment, the outer tube **102** has an outside diameter of about 0.050 inches and an inside diameter of about 0.038 inches. In this embodiment, the inner tube **104** has an outside diameter of about 0.036 inches and an inside diameter of about 0.023 inches. The radial wall clearance between the inner tube **102** and the outer tube **104** is about 0.001 inches and the diametric clearance is about 0.002 inches. The annulus between the two tubes must be substantially smooth, free from burrs, and free from contamination because the two tubes **102**, **104** beneficially need to translate along their longitudinal axis relative to each other over relatively long axial distances of about 50 to about 150-cm.

The inner tube **104** transmits force along its proximal non-slotted region **222** from the proximal end of the inner tube **104** to the lead in **228** where the force continues to be

propagated along the connected side **232** to the distal end **230**. The outer tube **102** transmits force along its proximal non-slotted region **212**. Longitudinal forces applied to the distal, flexible region with the slots **216** cause deformation of the outer tube in an asymmetrical fashion with the side of the outer tube **102** comprising the partial lateral slots **216** forming an outer curve if the slots **216** are expanded and an inside curve if the slots **216** are compressed. Forces to cause bending are preferably exerted such that the partial lateral slots **216** are compressed up to the point where the gap closes, but no further, however forces can also be exerted to expand the slots **216**, however limits on curvature are not in place because the lateral slots **216** can open in an unrestrained fashion except for the material properties of the outer tube **102**.

The disconnected side **234** of the inner tube **104**, separated from the connected side **232** by the longitudinal slot **226** and the lead in **228**, serves to maintain an undistorted tube geometry and provide resistance to deformation while helping to maintain the inner lumen **224** in a round configuration and provide a shoehorn or funnel effect to guide an obturator, guidewire, or stylet **140** therethrough as they are advanced distally. The disconnected side **234**, being separated from the force transmitting member **222** cannot provide any substantial longitudinal load bearing structure, although at its distal end, where it is integral or affixed to the distal end **230**, some tension load carrying capability exists. The inner tube **104** can be considered a split tube and does not carry a load in compression or tension along substantially the entire length of the disconnected side **234**. A main advantage of keeping the disconnected side **234** is to maintain the off-center positioning of the force transmitting member **222**.

The partial lateral slot **216** in the inner, or intermediate, tube **104** and the T-Slot **218** in the outer tube **102**, as well as the longitudinal slot **226** in the inner tube **104**, and the lead in slot **228** can be fabricated by methods such as, but not limited to, electron discharge machining (EDM), wire EDM, photo chemical etching, etching, laser cutting, conventional milling, or the like. In other embodiments, different slot configurations can also be employed, such as curved slots, complex slots, zigzag slots, or the like. The partial lateral slot **216** can be configured with a tongue and groove or dovetail design to prevent or minimize lateral movement or torquing of the outer tube **102** in the flexible region. The tongue and groove or dovetail (not shown) can be generally centered between two "T" slots, for example. The parts can be ganged and fixture such that, using wire EDM, for example, a plurality of tubes can be cut to reduce manufacturing costs. As many as 20 to 30 tubes, or more, can be fixtured, secured, and etched by the aforementioned methods.

FIG. 3 illustrates a side, cross-sectional view of the hub end **300** of a steerable guidewire. The hub end **300** comprises the outer proximal tube **110**, the inner tube **104**, a hub body **302**, a stopcock petcock **304** further comprising a petcock handle **308** and a petcock through bore **306**, a Luer lock fitting **312**, a keyed lumen **334**, a setscrew or pin **320**, a jackscrew body **316** further comprising a plurality of threads **328** and a central lumen **332**, a control knob **314** further comprising a plurality of threads **318**, a central lumen **330**, the protrusion **338**, and a circumferential recess **322**, an outer tube weld **324**, an orientation mark **340**, and an inner tube weld **326**. The hub body **302** can further comprise a plurality of recesses or complementary structures **336**. The hub **300** can also comprise an arrow pointer **310** to assist in

orientation of the direction of curvature at the distal end of the steerable guidewire by reference points on the hub 300.

Referring to FIG. 3, the petcock 304 is affixed to the petcock handle 308 by welding, integral fabrication, fasteners, adhesives, or the like. The petcock 304 is retained within a lateral through bore in the hub body 302, which is in the illustrated embodiment, tapered, using a locking “C” washer, fastener, screw, pin, or the like (not shown). The petcock 304 can be rotated about its longitudinal axis to align the through bore 306 with the axis and central lumen of the hub body 302 or it can be rotated sideways to shut off and seal the lumen against the flow of fluids. The Luer lock 312 can be affixed to, or integrally fabricated with, the hub body 302. The knob 314 is retained within the hub body 302 by the setscrew of pin 320 which prevents axial movement but permits rotational movement as constrained by the setscrew, projection, or pin 320 riding within the circumferential recess 322 which is integrally formed or affixed to the knob 314. The jackscrew body 316 is capable of axial movement within the hub body 302 but is restrained from rotation about the long axis by flats or features on the exterior of the jackscrew body 316 which are constrained by flats or features in the keyed lumen 334. The knob 314 comprises threads 328 on its internal lumen which engage with external threads 318 on the jackscrew body 316. Rotation of the knob 314 thus causes the jackscrew body 316 to move axially proximally or distally with mechanical advantage. Rotation of the knob 314 can be forced using manual action or using a motor or other mechanism (not shown). The proximal outer tube 110 can be affixed to the jackscrew body 816 by the outer tube weld 824. The inner tube 104 (which can also be called the intermediate tube) is affixed to the hub body 302 by the inner tube weld 326. The central lumen 224 of the inner tube 104 is operably connected to a central lumen of the hub body 302, the petcock through bore 306, and the lumen of the Luer fitting 312.

The knob 314 can comprise markings 340 to permit the user to visualize its rotary or circumferential position with respect to the hub body 302. These markings 340 can comprise structures such as, but not limited to, printed alphanumeric characters (not shown), a plurality of geometric shapes such as dots, squares, or the like, or the markings can comprise raised or depressed (embossed) characters of similar configuration as described for the printed markings. The knob 314 can comprise a number on each of the facets so the facets can be numbered from one to 6, in the illustrated embodiment. The knob markings 340 can further comprise raised structures, as illustrated, which can further be enhanced with contrasting colors for easy visualization. The number of facets can range from about three to about 50.

The knob 314 can further comprise one or more complementary structures affixed or integral thereto, such as a plurality of protrusions 338 that fit into detents 336 affixed or integral to the proximal end of the hub body 302. Such protrusions extending into detents in the hub body 302 can provide a ratcheting or clicking sound as well as providing resistance to inadvertent movement of the knob 314 once it is rotated to the correct location. The knob 314, in some embodiments, can be biased toward the hub body 302 to ensure that complementary structures such as the protrusions and detents come into correct contact. In other embodiments, the knob 314 can comprise a ratchet system to further control its rotary movement with respect to the hub body 302. In other embodiments, the knob 314 can comprise one or more detents (not shown) while the hub body 302 can comprise one or more complementary protrusions (not shown). It is beneficial that the knob 314 be moved only

when required by the user and not by accident or not when it is required to maintain its rotary position and, by consequence, the curvature at the distal end of the tubing. The number of ratchet locations, or low energy positions or setpoints, can range from about 2 per 360 degree rotation to about 20 with a preferred number of ratchet locations ranging from about 4 to about 12.

The hub body 302 can be fabricated from biocompatible metals such as, but not limited to, stainless steel, titanium, nickel coated brass, cobalt nickel alloy, and the like, although it could also be fabricated from polymeric materials in a less expensive format. The knob 314 can be fabricated from the same metals as the hub body 302 but it can beneficially be fabricated from biocompatible polymers such as, but not limited to, polyamide, polyimide, polyvinyl chloride (PVC), acrylonitrile butadiene styrene (ABS), acetal polymers, polycarbonate, polysulfone, PEEK, Hytrel®, Pebax®, and the like. The petcock 304 and petcock handle 308 can be fabricated from the same materials as the knob 314, or it can be different materials. The jackscrew body (or traveler) 316 can be fabricated from the same materials as the hub body 302, or from different materials, but must be able to be strongly affixed to the outer tube 102.

The arrow pointer 310 can be affixed to the hub body 302 or other component. The arrow pointer 310 is used to indicate the direction of bending or deflection at the distal end of the steerable guidewire by reference points on the hub but due to torsional effects on such a long device as a guidewire, the primary guide for orientation will be the fluoroscopic or X-Ray images taken of the distal end of the steerable guidewire, in vivo. The hub system 300 illustrated in FIG. 3 is not detachable or releasable from the proximal end tubes 110 and 104. In other embodiments such as that of FIG. 1, the hub system 300 can be made to slide onto the tubes 110, 104 and clamp by means of locking mechanisms. In yet other embodiments, the hub 300 can be made to split open along its axis and then re-close and latch over the proximal ends of the tubes 110, 104.

FIG. 4 illustrates a side view, in partial breakaway, the distal end 400 of a steerable guidewire. The distal end 400 comprises the distal outer tubing 102 further comprising the lateral partial slits 216 and the intermediate (or inner) tubing 104 further comprising the longitudinal slit 226 and the distal inner tube tip 230. The slotted portion of the inner tube defines the flexible region of the inner tube, and the snake cut segment of the outer tube defines the flexible region of the outer tube. The flexible region of the inner tube is disposed within the longitudinal extent of the flexible region of outer tube. A weld 402 affixes the distal end of the outer tubing 102 to the connected side 232 of the intermediate tubing, such the inner tube and outer tube are longitudinally fixed to each other at this point. Other longitudinal fixation mechanisms, (such as interleaved flanges on each tube) which allow relative rotation of the inner and outer tubes may be used. The distal end 400 can further comprise one or more separate radiopaque markers 404 and a nose cone or distal fairing 118, which may or may not comprise a central lumen. The distal outer tube 102 and the inner tubing 104 are rotated about the longitudinal axis such that the connected side 232 of the inner tube 104 is generally aligned with, and affixed or welded 402 to, the distal outer tubing 102 on the side comprising the partial lateral slits 216. The width of the partial lateral slits 216, the T-slots 218, and the longitudinal slot 226 can range from about 0.001 to about 0.050 inches with a preferred range of about 0.005 to about 0.020 inches. In the illustrated embodiment, the slits 216, 218, and 226 are about 0.010 inches. The width of the partial lateral slits 216

on the outer tube **102** can be used, in compression to provide at least some limit to how much the distal outer tube **102** can bend in compression along the side comprising the partial lateral slits **216**. Note that the inner tube **104** extends beyond the distal end of the distal outer tube **102**. In the illustrated embodiment, the inner tube **104** extends about 10 mm to about 20 mm beyond the distal end of the distal outer tube **102**. This construction provides for reduced device complexity, increased reliability of operation, and reduced manufacturing costs relative to other steerable devices. The steerable guidewire, in the embodiments presented herein, has high column strength, and resistance to torque.

The distal end **400** of the steerable guidewire can be generally fabricated from metals with sufficient radiopacity or radio-denseness that they are clearly visible under fluoroscopic or X-ray imaging. However, if this is not the case, additional radiopaque markers **404** can be affixed to the outer tube **102**, the inner tube **104**, or both. These radiopaque markers **404** can comprise materials such as, but not limited to, tantalum, gold, platinum, platinum iridium, barium or bismuth compounds, or the like. The radiopaque markers **404** can be beneficially oriented in an asymmetrical manner, as illustrated, to denote the direction of bending to an observer viewing an X-ray image of the distal end **400**.

Close tolerances between the internal diameter of the outer tube **102** and the outside diameter of the inner tube **104**, ranging from a radial gap of between about 0.0005 inches to about 0.008 inches, depending on diameter cause the two tubes **102** and **104** to work together to remain substantially round in cross-section and not be ovalized, bent, kinked, or otherwise deformed. This is especially important in the flexible region comprising the partial lateral cuts **216** on the distal outer tube **102** and the longitudinal slot **226** in the inner or inner tube **104**. The two tubes **102** and **104** can be fabricated from the same materials or the materials can be different for each tube **102**, **104**. Materials suitable for tube fabrication include, but are not limited to, stainless steel, nitinol, cobalt nickel alloy, titanium, and the like. Certain very stiff polymers may also be suitable for fabricating the tubes **102**, **104** including, but not limited to, polyester, polyimide, polyamide, polyether ether ketone (PEEK), and the like. The relationship between the inner tube **104**, the distal outer tube **102**, and the slots **216**, **218**, **226**, **228** serve to allow flexibility and shaping in high modulus materials such as those listed above, which are not normally suitable for flexibility. The internal and external surface finishes on these tubes **102**, **104** are preferably polished or very smooth to reduce sliding friction between the two tubes **102**, **104** because of their very small cross-sections and their relatively long lengths. Lubricants such as, but not limited to, silicone oil, hydrophilic hydrogels, hydrophilic polyurethane materials, PFA, FEP, or polytetrafluoroethylene (PTFE) coatings can be applied to the inner diameter of the distal outer tube **102**, the outer diameter of the inner tube **104**, or both, to decrease sliding friction to facilitate longitudinal relative travel between the two tubes which is necessary for articulating the flexible, slotted region near the distal end **400** of the articulating, deflectable, or steerable guidewire. The exterior surface of the distal outer tube **102** can be covered with a polymeric layer, either substantially elastomeric or not, which can cover the slots **216**, **218**, etc. and present a smoother exterior surface to the environment as well as optionally maintaining a closed fluid path through the lumen of the guidewire. The exterior surface can be affixed or configured to slip or slide over the exterior of the outer tube **102**.

The weld **402** affixes the distal outer tube **102** to the intermediate or inner tube **104** such that they cannot move relative to each other along the longitudinal axis at that point. However, since the two tubes **102**, **104** are affixed to each other on the side of the distal outer tube **102** containing the partial lateral slots or gaps **216**, compression or expansion of those gaps **216** can be accomplished by moving the weld **402** by relative movement of the inner tube **104** and the outer tube **102**. The weld transmits the force being carried by the connected side **232** of the inner tube **104** to the slotted side of the distal outer tube **102**. The inner tube **104** may be an intermediate tube **104** if another tube, wire, stylet, or catheter is passed through its internal lumen **224**.

In other embodiments, since the inner tube **104** is split **226** lengthwise in the flexible region, a portion, or the entirety, of the distal end of the inner tube **104** can be affixed, adhered, welded, fastened, or otherwise attached to the distal outer tube **102** and functionality can be retained. The distal end **230** of the inner tube **104** can, in some embodiments be retained so as to create a cylindrical distal region **230** in the inner tube **104** and this entire cylindrical distal region **230**, or a portion thereof that does not project distally of the distal end of the outer tube **102** can be welded to the outer tube **102** around a portion, or the entirety of the circumference of the outer tube **102**. If only a portion of the inner tube **104** is welded to the distal outer tube **102**, then the weld is beneficially located, approximately centered, on the side of the distal outer tube **102** comprising the partial lateral slots **216**. The cylindrical distal region **230** is a beneficial construction, rather than completely cutting the inner tube **104** away on one side, since the distal region **230** projects distally of the distal end of the distal outer tube **102** to form the tip of the steerable guidewire further comprising a nose cone or distal fairing **118**. The distal nose cone or fairing **118** can be affixed to the distal outer tube **102**, the distal end **230** of the inner tube **104**, or both, using methodology such as, but not limited to, fasteners, welds, adhesive bonding, and the like.

In some embodiments, one of the welds, all of the welds, or a portion of the welds can be completed using techniques such as, but not limited to, TIG welding, laser welding, silver soldering, fasteners, adhesives, plasma welding, resistance welding, interlocking members, or a combination thereof. Laser welding is beneficial because it is highly focused and can be located with high accuracy. These welds include the weld **402** at the distal end that connects the inner tube **104** and the distal outer tube **102** as well as the welds at the proximal end connecting the inner tube **104** to the hub and the distal outer tube **102** to the traveler of the jack-screw **316**.

FIG. 5 illustrates an oblique external view of the proximal end **500** of the steerable guidewire comprising the outer tube **110**, the knob **314**, the hub body **302**, the arrow pointer **508** further comprising the pointed end **504**, a stopcock body **506**, the petcock **304**, the petcock handle **308**, and the Luer fitting **312** further comprising a locking flange **502**. In this embodiment, the hub can be configured to be removable or it can be configured to be permanently affixed to the proximal end of the outer proximal tubing **110** and the inner tubing **104** (not shown).

Referring to FIG. 5, the pointed end **504** of the arrow pointer **508** can be integrally formed with the arrow pointer **508**, or it can be affixed thereto. The arrow pointer **508**, which is optional, can be integrally formed with the hub body **302**, or it can be affixed thereto using fasteners, welds, adhesives, brazing, soldering, or the like. The stopcock body **506** can be integrally formed with the hub body **302** or it can

be affixed thereto using fasteners, welding, soldering, brazing, adhesives, threads, bayonet mounts, or the like. Referring to FIGS. 3 and 5, the lumen of the Luer fitting 512 is operably connected to the through bore of the petcock 304 if the petcock 304 is aligned therewith (as illustrated), or the petcock 304 can be rotated about an axis to misalign the through bore of the petcock 304 with the Luer fitting 512 and prevent fluid flow or passage of solid material therethrough. The knob 314 can be round, shaped as a lever, it can comprise knurls, facets (as illustrated), or it can comprise a plurality of projections which facilitate grabbing and rotation by the user. Circumferential motion of the knob 314 about its longitudinal axis is preferably and beneficially smooth but with sufficient friction to maintain its position in any desired configuration.

FIG. 6 illustrates the distal end 400 of the steerable guidewire in a curved configuration. The distal end 400 comprises the distal outer tube 102, the inner tube 104, the outer tube lumen 214, the nose cone 118, the plurality of outer tube longitudinal cuts or slots 218, and the plurality of outer tube partial lateral cuts 216.

Referring to FIG. 6, the outer tube partial lateral cuts 216 represent spaces that close up when the side of the tube in which the lateral cuts 216 are located is placed in compression. Such compression is generated by pushing the outer tube 102 distally relative to the inner tube 104. When the partial lateral cuts 216 gaps close, further compression is much more difficult because the outer tube 102 stiffens substantially when no further gap exists for compression. The composite structure, with the inner tube 104 nested concentrically inside the outer tube 102 is relatively stiff and resistant to kinking no matter what amount of curvature is being generated.

Preferred radius of curvatures for the distal end can range from about 0.25 inch to about 6 inches, with a preferred range of about 0.5 inches to about 2 inches and a more preferred range of about 0.5 to about 1.5 inches. The radius of curvature need not be constant. The proximal end of the flexible region can have the partial lateral cuts 216 spaced more widely than those at the distal end of the flexible region, causing the distal end to bend into a tighter radius than, the proximal end of the flexible region. In other embodiments, the distal region can be less flexible than the proximal end of the flexible region.

The partial lateral cuts 216, and the "T"-slots in the outer tube 102 are beneficially treated using etching, electropolishing, passivation, sanding, deburring, machining, or other process to round the external edges of the partial lateral cuts 216. Thus, the edges are blunted or rounded so they are not sharp such as to cause the steerable guidewire to dig, skive, or shave material from the inside of a catheter, dilator, or obturator.

FIG. 7A illustrates a top view of another embodiment of an outer tube 700 in the region of the distal, flexible section, wherein the outer tube 700 comprises a plurality of partial lateral cuts or slots 706 further comprising a dovetail 702. The dovetail 702 creates a groove 702 and further comprises a peg or projection 704 that rides or is circumferentially constrained within the groove 702 as long as the outer tube 700 is neutrally forced, or forced in compression on the side of the partial lateral cuts or slots 706. The projection 704 riding within the dovetail groove 702 provides for torque resistance and torsional rigidity in the area of the dovetail 702.

FIG. 12B illustrates a side view of the outer tube 700 in the region of the distal, flexible section, wherein the outer tube 700 comprises the partial lateral slots 706, the dovetail

702 further comprising the projection 704, and the "T" slots 218. The T-slots 218 are optional or they can be configured differently.

The steerable guidewire can be used in the cardiovascular system, the pulmonary system, the gastrointestinal system, or any other system comprising tubular lumens, where minimally invasive access is beneficial. The steerable guidewire of the present invention is integral and steerable. It is configured to be used with other catheters that may or may not be steerable, but the steerable guidewire disclosed herein does not require external steerable catheters or catheters with steerability to be steerable as it is steerable or articulating on its own. The steerable guidewire is capable of bending and unbending a practically unlimited number of times. The steerable guidewire is especially useful with catheters that are not steerable since the steerable guidewire comprises its own steering system.

The steerable guidewire can be removed from the lumen of a catheter following completion of its task. Without removal of the steerable guidewire, the lumen is compromised and the capacity of the sheath to introduce catheters is reduced, given a certain outside diameter. This device is intended for use with catheters and is not intended for use as integral to a catheter. The steerable guidewire device steers itself and can steer a catheter but is not a replacement for a steerable catheter.

The steering mechanism disclosed herein can be used to steer other types of catheters, guide catheters, introducers, sheaths, guidewires, punches, needles, or even obturators that are placed within the aforementioned devices, with high degree of control over long lengths up to 250 cm or more while requiring less wall thickness and thus allowing for larger internal lumens than steerable devices of the prior art with the same outside diameter. Typical sheaths can have internal lumens with capacities of, for example, 3-Fr to 12-Fr and still maintain very thin walls of around 1-Fr. While smaller catheters or guide catheters with lumens in the range of about 2-Fr to 5-Fr can have even smaller wall thicknesses, depending on the materials used to construct the walls of the sheath. Some sheath constructions can comprise composite materials such as an inner tube fabricated from metal and an outer tube fabricated from metal with a polymeric exterior coating. The inner tube can further be coated with an interior liner of, for example PTFE, or other fluoropolymers (PFA, FEP), Parylene, Pebax®, Hytrel®, polyimide, polyamide, PET, or the like, to create certain reduced frictional properties, electrically insulating properties, or both. These coatings or liners can range in thickness from about 0.0001 to about 0.005 inches, with a preferred thickness range of about 0.0005 to 0.002 inches.

The steering mechanism disclosed herein, comprising two or more nested axially elongate cylindrical tubes moving relative to each other only along the longitudinal axis, can provide a high degree of precision, repeatability, force, column strength, torsional control, and the like, in a configuration with extremely thin walls and large inside diameter (ID) to outside diameter (OD) ratio. One of the tubes comprises partial lateral cuts or complex lateral gaps and the other tube comprising a split running substantially the length of the flexible region. The disconnected side of the slit tube can be removed so that only a partially formed, connected side remains. However, in preferred embodiments, the disconnected side, which is actually retained at the distal end, is not removed but serves to fill space within the lumen of the outer tube 102 to prevent kinking, improve column strength, prevent lumen collapse and provide for guiding of central stylets or catheters. Prior art devices require greater

wall thickness, which reduces the size of the internal lumen relative to a given outside diameter, or they do not have the same degree of precise movement at the distal tip under control from the proximal end of the device.

FIG. 8 illustrates a side view of the distal end 400 the steerable guidewire advanced through a central lumen 812 of a dilator or obturator 810 of a guide catheter 814. The steerable guidewire distal end 400 comprises the outer tube 102, comprising the plurality of partial lateral cuts 216, and the inner tube 104, comprising a distal end 220. The distal end 220 comprises, or is terminated by a rounded, blunted, atraumatic distal end 806. The steerable guidewire 400 can further comprise a central lumen (not shown). The guide catheter 814 further comprises a central lumen 816.

The outer tube 102 can be modified to adjust stiffness. It can be preferential to increase the resistance to bending moving distally to proximally on the outer tube 102. This increase in bending resistance contravenes the tendency of the outer tube to bend more severely at the proximal end of the flexible region than in the distal region. It is possible to configure the bending so that the bend radius is approximately constant or such that a greater curvature (smaller radius of bending) is generated moving toward the distal end of the bendable region. The partial lateral slots 216 can be cut with reduced depth more proximally to increase the resistance to bending imparted by the outer tube 102. The partial lateral slots 216 can be cut more narrowly in the more proximal regions to reduce the distance the slot 216 can close. The T-slots 218 can be reduced in length or removed in the more proximal regions of the flexible region of the outer tube 102. Elastomeric bumpers or fillers can be added to some of the partial lateral slots 216 to reduce the amount the partial lateral slots 216 can compress. Once the partial lateral slots 216, associated with the T-slots 218 have closed under bending of the outer tube 102, further bending is resisted and is substantially arrested. By tailoring the width and spacing of the partial lateral slots 216, a specific final curvature can be tailored for a given catheter.

FIG. 9A illustrates the outer tube 102 comprising the lumen 214, the proximal tube wall 212, the plurality of partial lateral slots 216, the plurality of T-slots 218, a short partial lateral slot 902, a slightly longer partial lateral slot 904, and a standard length lateral slot 216 but with a shortened T-slot 906.

Referring to FIG. 9A, the most proximal partial lateral slot 902 penetrates less than the standard partial lateral slots 216. The second (moving distally) partial lateral slot 904 is slightly longer than slot 902 and therefore is more flexible in that region and requires less force to generate bending. The third partial lateral slot comprises the shortened T-slot 906 which reduces the ability of the tubing to bend given a constant bending force.

FIG. 9B illustrates the inner tube 104 comprising the lumen 224, the proximal region 222, the connected side 232, the distal end 230, the rounded tip 118, and a beveled lead-in 910 at the proximal end of the distal end 230.

Referring to FIG. 9B, the proximal end of the disconnected region can be moved distally to increase the stiffness of the inner tube 104 in a specific region, generally the most proximal part of this distal, flexible region.

In certain preferred embodiments, it is beneficial that the inner tube 104 can sustain compression to generate bending of the outer tube 102 at the distal end back to straight after being curved and even to bend beyond straight in the other (or opposite) direction. In order to sustain compression, it is beneficial that the disconnected side 234 be separated from the connected side 232 at or near substantially the center or

midpoint of the tubing. Depending on the width of the slot 226 separating the disconnected side 234 from the connected side 232, the location of the slot can be offset from the midpoint but this is dependent on the wall thickness of the inner tube 104 and the angle of the slotting. In a preferred embodiment, interference exists between the disconnected side 234 and the connected side 232 such that the disconnected side and force transmitting member cannot move substantially inward, a situation that would have negative effects of obstructing the lumen, restricting fluid flow there-through, trapping stylets or other catheters that need to move longitudinally therein, or buckling sufficiently to prevent application of longitudinal compression forces on the connected side 232.

FIG. 10A illustrates a lateral cross-sectional view an inner tube 104 nested inside an outer tube 102 and separated from the outer tube 104 by a radial gap 1002 in the flexible region of a steerable guidewire wherein the inner tube 104 is separated by a split or gap 226 into two approximately or substantially equal parts, a connected side 232 and a disconnected side 234, approximately (or substantially) at the midline or centerline of the cross-section.

FIG. 10B illustrates a lateral cross-sectional view an inner tube 104 nested inside an outer tube 102 and separated from the outer tube 104 by a radial gap 1002 in the flexible region of a steerable guidewire wherein the inner tube 104 is separated by a split or gap 226 into two substantially unequal parts, a connected side 232 and a disconnected side 234, substantially offset from the midline or centerline of the cross-section.

Referring to FIGS. 10A and 10B, the disconnected side 234 is retained in close proximity to the outer tube 102 by its stiffness and its inability to deform such that the edges of the disconnected side 234 can pass beyond the edges of the connected side 232 and thus the two sides 232 and 234 are retained radially displaced from centerline. If the gap 226 were too large or either side 232, 234 were small enough to fit within the edges of the other side, then displacement of one side toward the centerline and confounding of the off-center orientation of the connected side 232 or 234 would occur leading to buckling of the connected side 232 in compression and inability to straighten out a bent steerable guidewire. Another problem might be loss of torqueability and predictability of the direction of bending. Both embodiments shown in FIGS. 16A and 16B maintain circumferential and radial orientation of the inner tube connected side 232 relative to the disconnected side 234 and promote high precision deflection of the distal tip.

In preferred embodiments, the radial gap 1002 is minimized and is retained between about 0.0005 to 0.002 inches when the steerable guidewire is about 0.035 inches in outside diameter. Furthermore, the split or gap 226 should be as minimal as possible and in preferred embodiments can range from about 0.0005 inches to about 0.003 inches with a gap of about 0.0005 to 0.02 inches being most preferable.

FIG. 11 illustrates a side, partial breakaway view of the distal end of a steerable guidewire 1100 as well as a portion of the intermediate region. The steerable guidewire 1100 comprises the inner tube 104, the coiled intermediate outer tube 108, the distal outer coil 1102, the nose cone 118, the backbone 1104, the polymeric outer coating 106, and the distal coil spaces 1110.

The polymeric outer coating 106 can extend the entire length of the steerable guidewire 1100 (or 100) or it can extend only over a portion of the length and can correspond to certain sections such as the proximal section, one or more intermediate section 108, the distal region 1102, or a com-

bination thereof. The polymeric outer region can comprise an elastomer such as, but not limited to, Hytrel, Pebax, polyurethane, silicone rubber, or the like, and can be coated with an additional anti-friction coating such as silicone oil, silicone grease or gel, fluoropolymer, polyimide, or the like.

The distal coil **1102** is affixed, at its proximal end, to the distal end of the intermediate coil **108** and at its distal end to the nose cone **118**. The inner tube **104** is affixed to the distal coil **1102** in a region proximate the nose cone **118** such that most or nearly all the distal coil is controlled in expansion and contraction by the inner tube **104**. The distal coil **1102** comprises the spaces **1110** which can range in magnitude from 0.0005 inches to about 0.020 inches or greater. In the illustrated embodiment, the coil spaces **1110** are about equal in width to the coil element diameter. The coil element diameters can range from about 0.0005 inches to about 0.010 inches and preferentially ranges from about 0.001 inches to about 0.007 inches in diameter. The coil materials can comprise materials such as, but not limited to, nitinol, polyimide, stainless steel, titanium, cobalt nickel alloy, or the like. The coil materials beneficially comprise material properties of low malleability and high spring hardness.

Referring to FIGS. **11** and **2**, the backbone **1104** is located on the side **234** of the steerable guidewire **1100** where the inner tube **104** is disconnected from more proximal structures. Thus, axially oriented forces transmitted through the connected side **232** cause the spring coil **1102** to compress or expand longitudinally with more freedom and less restriction on the connected side **232**, as imposed by the backbone **1104**, than on the disconnected side **234**. This results in an asymmetric force loading on the distal end and causes the distal end to deflect away from the longitudinal axis under control from the proximal end of the steerable guidewire **1100**.

FIG. **12** illustrates the distal end of a steerable guidewire **1200** comprising the inner tube **104** further comprising the longitudinal slot **226**, the intermediate outer tube **108**, the polymeric covering **106**, the nose cone **118**, a distal outer tube **1202** further comprising a plurality of lateral gaps **1210** and a backbone **1208**.

Referring to FIG. **12**, the distal outer tube **1202** can be fabricated as a tube comprising the slots **1210** or gaps that are imparted by way of EDM, wire EDM, laser cutting, photochemical etching, conventional machining, or the like. The proximal end of the distal outer tube **1202** is affixed to the distal end of the intermediate outer tube **108**. The distal end of the distal outer tube **1202** is affixed to the tip or nose cone **118**. The distal end of the outer tube **1202** is also affixed to the inner tube **104** substantially distal to the distal end of the longitudinal slot **226** to prevent rotational and lateral relative movement at that point. The backbone **1208** forces asymmetric lengthening and compression of the gaps **1210** thus generating a lateral bend or curve out of the longitudinal axis in the distal outer tube **1202**.

The embodiments presented herein describe a system that does not use pull wires. No side lumens are required in either the outer tube or the inner tube. Such side lumens, as found in certain prior art catheters, require extensive cross-sectional area be used to surround the side lumens and take away from the potential area for the central lumen since the outside extent of the catheter is limited. The use of pull wires requires such as those in certain prior art catheters, retaining these structures along one side of the outer tube may be difficult or impossible. Side lumens or channels are necessary to retain a pull wire or control rod in the correct location so as to provide correct off center forces to bend the distal

end. The side lumens are also necessary to keep the control rod or pull wires out of the central lumen which needs to remain open and substantially circular. The system disclosed herein, however, retains a high degree of column strength, maximum torqueability, the largest possible central lumen, and a very strong control and steering function or capability. Furthermore, the side lumens or channels are necessary to maintain spatial (rotational orientation) for the articulating distal end of the device. Without the side lumens or channels permitting axial slidability but generating radial retention, the pull wires or pushrods would be free to migrate around within the central lumen of the device and could bend the device in an unwanted direction. Long guidewires with relatively small cross-sectional areas are highly subject to torque and rotational misalignment and some method must be employed to retain the correct circumferential location of the articulating apparatus.

Furthermore, a pull-wire as used in prior art devices is incapable of generating compression against the distal end of the device so a pull-wire could not, under compression, move or articulate the distal end of the device. The pull-wire, under tension, can move or articulate the distal end and would require some sort of counterforce such as an opposing pull-wire, shape memory metal, or spring return biasing to move the distal end in the reverse direction.

However, a tubular or cylindrical (substantially no lumen) central control device can maintain its structure in compression, maintain circumferential location within the outer cylindrical, axially elongate tube, maintain precise control, maintain sufficient tensile strength to exert forces, and maintain a central lumen larger than any other type of steerable device. The resistance to buckling occurs even when the inner tube is slotted longitudinally because the inner tube is constrained within the outer tube using very tight tolerances that will not let the inner tube bend out of its straight orientation, even under compression.

Thus, the inner tube can be configured with a vanishingly small lumen, or it can be replaced with a solid rod or wire. The inner tube can comprise a filler, for example using one or more wires. The inner tube can comprise filler material such as polymers, metals, ceramics, or the like. However, whether an inner tube or a solid rod or wire is used, this component is split or separated longitudinally in the flexible region near the distal end, proximate also to the flexible region of the outer tube, so as to apply an unbalanced force proximate the distal end of the outer tube.

Furthermore, the outer tube can be affixed to the hub structure and the inner tube can be affixed to the jackscrew. Thus, when the control mechanism is activated, the inner tube moves relative to the stationary outer tube, rather than the outer tube moving relative to the stationary inner tube. While this involves a more complex hub structure, it is certainly possible to fabricate the steerable guidewire this way and may include certain advantages.

While the preferred embodiments of the devices and methods have been described in reference to the environment in which they were developed, they are merely illustrative of the principles of the inventions. The elements of the various embodiments may be incorporated into each of the other species to obtain the benefits of those elements in combination with such other species, and the various beneficial features may be employed in embodiments alone or in combination with each other. Other embodiments and configurations may be devised without departing from the spirit of the inventions and the scope of the appended claims.

We claim:

- 1. A steerable guidewire comprising:
 - an outer tube characterized by a proximal end, a distal end, and a flexible region at said distal end of the outer tube, said flexible region also characterized by a proximal and a distal end; and
 - an inner tube characterized by a proximal end and a distal end, and a flexible region near said distal end of the inner tube;
 - said inner tube being disposed within the outer tube, extending from the proximal end of the outer tube to the distal end of the outer tube, and terminating distally at the distal end of the outer tube, said inner tube longitudinally fixed to the outer tube at a point in the outer tube proximate the distal end of the flexible region of the outer tube; wherein
 - the flexible region of the outer tube comprises a segment of the outer tube which is snake-cut with a plurality of radially oriented slots in the wall of the outer tube, said radially oriented slots being substantially radially aligned along one side of the outer tube; and
 - the flexible region of the inner tube comprises a segment of the inner tube with a longitudinally oriented slot; wherein
 - the flexible region of the inner tube comprising the longitudinally oriented slot disposed in the inner tube is split lengthwise by the longitudinally oriented slot such that it comprises a split tube with a free side (234) and a connected side (232), with the longitudinally oriented slot running longitudinally between the free side (234) and said connected side (232).
- 2. The steerable guidewire of claim 1, further comprising an angled lead-in (228) communicating from the longitudinally oriented slot through a side wall of the inner tube, wherein said angled lead-in is disposed at an angle between -80° to +2° from a longitudinal axis of the inner tube.
- 3. The steerable guidewire of claim 1, further comprising an angled lead-in (228) communicating from the longitudinally oriented slot through a side wall of the inner tube, wherein said angled lead-in is disposed at an angle between +5° to +20° from a longitudinal axis of the inner tube.
- 4. The steerable guidewire of claim 1, further comprising an angled lead-in (228) communicating from the longitudinally oriented slot through a side wall of the inner tube, wherein said angled lead-in is disposed at an angle between +8° to +15° from a longitudinal axis of the inner tube.

- 5. The steerable guidewire of claim 2, wherein the angled lead-in (228) is disposed proximal to the flexible region of the outer tube.
- 6. The steerable guidewire of claim 1 further comprising:
 - a hub affixed to the proximal end of the inner tube, wherein the hub comprises an internal lumen capable of receiving a jack-screw traveler element and preventing said jack-screw traveler element from rotating about the longitudinal axis of the hub, wherein the inner tube is constrained not move relative to the hub;
 - a jack-screw traveler element affixed to the proximal end of the outer tube, wherein the jack-screw traveler element comprises a traveler thread on at least a portion of its outer surface, and further wherein the outer tube can move axially relative to the hub and inner tube in response to movement of the jack-screw traveler element;
 - a knob affixed to the hub, capable of being rotated by a user, wherein the knob comprises a knob thread on an inner lumen such that the knob thread and the traveler thread engage; and
 - a fixation element configured to prevent longitudinal motion of the knob relative to the hub, when the knob is rotated.
- 7. The steerable guidewire of claim 1, wherein the longitudinally oriented slot of the inner tube terminates at one end in an angled lead-in communicating from the longitudinally oriented slot, at an angle to a longitudinal axis of the inner tube, and opening through the side wall of the inner tube.
- 8. The steerable guidewire of claim 1, wherein the inner tube is fixed to the outer tube at a point radially aligned with the radially oriented slots.
- 9. The steerable guidewire of claim 1, wherein the longitudinally oriented slot of the inner tube terminates at its proximal end in an opening through the side wall of the inner tube.
- 10. The steerable guidewire of claim 3, wherein the angled lead-in (228) is disposed proximal to the flexible region of the outer tube.
- 11. The steerable guidewire of claim 4, wherein the angled lead-in (228) is disposed proximal to the flexible region of the outer tube.
